Milestone 1: Data Selection and EDA

Business Problem Narrative

Title: Strategic Home Renovation Investment Advisor for Real Estate Flippers

Problem Statement and Business Context

Real estate investment firms and individual house flippers face a critical challenge: deciding which home improvements will give the maximum return on investment (ROI) while buying and renovating properties for resale. Right now, many investors depend on intuition or general market trends, which often causes over-investment in low-impact features or under-investment in high-impact renovations.

Target Organization:
A mid-sized real estate investment company in Ames, Iowa, focused on buying undervalued properties, renovating them, and selling at profit. The company handles 20–30 properties per year, with renovation budgets between Dollar 20,000 and 100,000 per property.

Business Problem: The company needs a data-driven decision support system to predict home sale prices using property characteristics. The focus is to identify which features—both inherent (location, lot size) and improvable (quality ratings, square footage, garage capacity)—have the strongest impact on sale price. This will help the company to:

1. Accurately estimate post-renovation value of potential acquisitions
2. Prioritize renovation investments for maximum property value
3. Identify undervalued properties where strategic improvements give highest ROI
4. Make informed acquisition decisions by predicting fair market value

Model Target: Predict the `SalePrice` (continuous variable) of residential properties in Ames, Iowa, based on 79 predictor variables including property characteristics, quality ratings, square footage, and neighborhood factors.

Expected Business Impact: By implementing this predictive model, the investment firm can:

- Reduce renovation cost overruns by an estimated 15–20% through targeted improvements
- Increase average profit margin per property by 10–15% through optimal feature prioritization
- Reduce time-to-market by avoiding unnecessary renovations
- Improve acquisition strategy by identifying the most undervalued properties with renovation potential

This model will serve as the foundation for a decision support dashboard where investors can input property characteristics and receive both price predictions and renovation recommendations ranked by expected value impact.

Data for this analysis is downloaded from https://www.kaggle.com/competitions/house-prices-advanced-regression-techniques/data

```

In real estate data, missing ≠ unknown. Missing often means "feature doesn't exist." We create a few binary indicators and derived features to capture this.

In [52]:

```
# Derived features for train set
train_df["TotalSF"] = (train_df["TotalBsmtSF"] + train_df["1stFlrSF"] + train_df["2ndFlr

# Graph 1: Distribution of Sale Prices
plt.figure(figsize=(7, 3))
sns.histplot(train_df['SalePrice'], bins=30, kde=True, color='skyblue')
plt.title('Distribution of Sale Prices', fontsize=16)
plt.xlabel('Sale Price', fontsize=14)
plt.ylabel('Frequency', fontsize=14)
plt.show()
```

Graph 1 Analysis: Distribution of Sale Prices

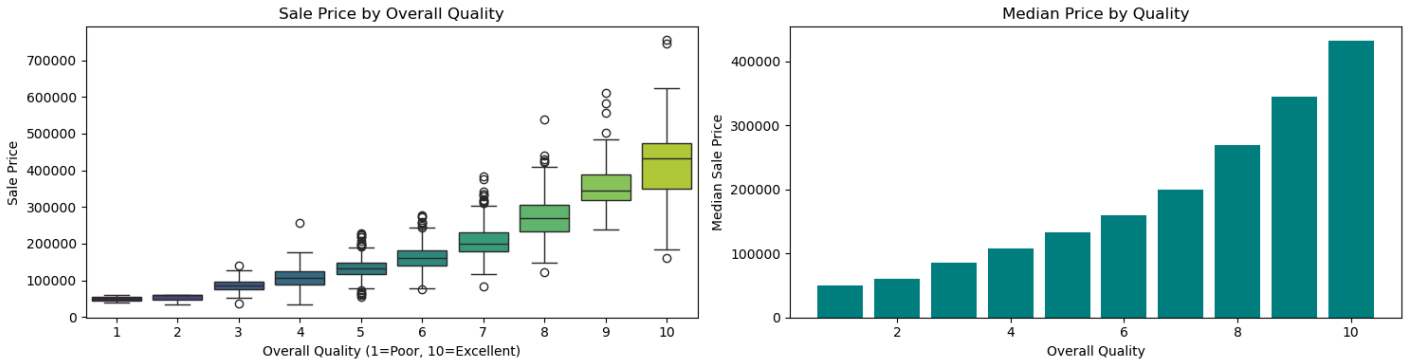
Sale prices exhibit strong right-skewness (1.88), with most properties clustered in the Dollars 100K-250K range. The median (Dollars 163K) sits below the mean (Dollars 180,921), indicating luxury outliers pull the average upward. This concentration suggests the Dollars 100K-250K range represents the safest investment zone with abundant comparable sales data. The skewness necessitates log-transformation for linear modeling to improve prediction accuracy and address heteroscedasticity.

In [54]:
```
# Graph 2 & 3: Overall Quality vs Sale Price
fig, axes = plt.subplots(1, 2, figsize=(15, 4))

# Box plot
sns.boxplot(data=train_df, x="OverallQual", y="SalePrice",
    palette="viridis", ax=axes[0])
axes[0].set_xlabel("Overall Quality (1=Poor, 10=Excellent)")
axes[0].set_ylabel("Sale Price")
axes[0].set_title("Sale Price by Overall Quality")

# bar chart
quality_stats = train_df.groupby("OverallQual")["SalePrice"].median()
axes[1].bar(quality_stats.index, quality_stats.values, color="teal")
axes[1].set_xlabel("Overall Quality")
axes[1].set_ylabel("Median Sale Price")
axes[1].set_title("Median Price by Quality")

plt.tight_layout()
plt.show()
```



Graph 2 & 3 Analysis: Overall Quality vs Sale Price

OverallQual demonstrates the strongest correlation (0.791) with sale price. Each quality point adds approximately Dollars 30K-40K in median value, with Quality 7-8 jumps yielding an estimated 50K gains. Acquiring Quality 5-6 properties and renovating to Quality 7-8 offers optimal ROI of Dollars 30K-50K investments can generate dollars 80K-100K value additions. Quality upgrades represent the highest impact renovation strategy for mid market properties.

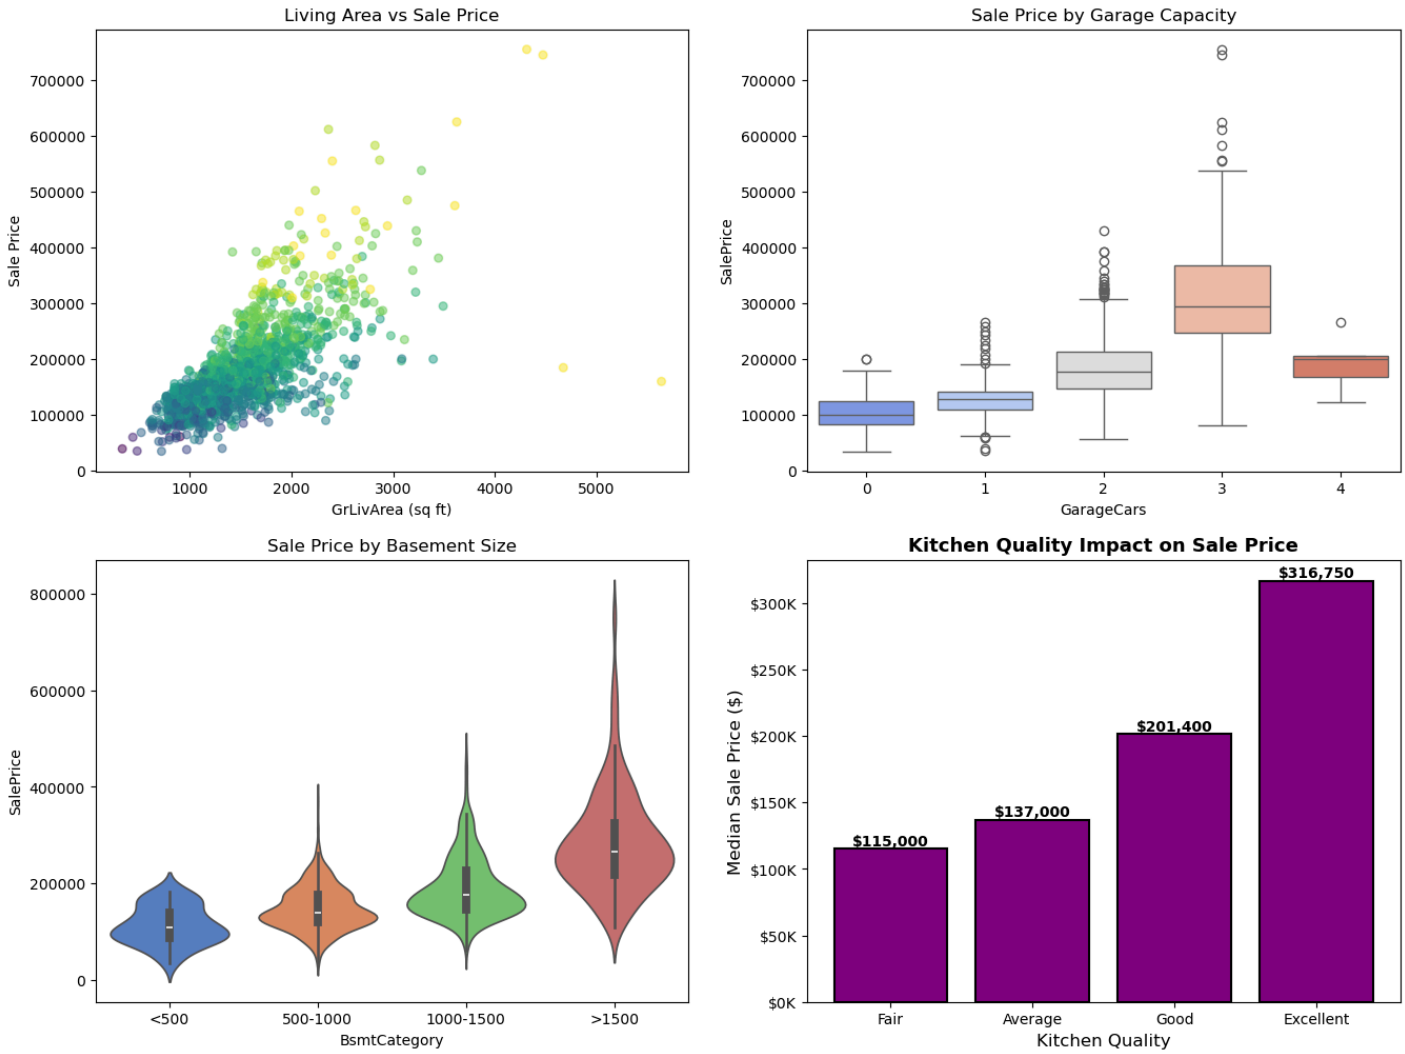
    color='purple',
    edgecolor='black',
    linewidth=1.5
)

# Add value labels on bars for clarity
for bar in bars:
```

```
    height = bar.get_height()
    axes[1, 1].text(bar.get_x() + bar.get_width()/2., height,
                    f'${height:,.0f}',
                    ha='center', va='bottom', fontsize=10, fontweight='bold')

axes[1, 1].set_ylabel('Median Sale Price ($)', fontsize=12)
axes[1, 1].set_xlabel('Kitchen Quality', fontsize=12)
axes[1, 1].set_title('Kitchen Quality Impact on Sale Price', fontsize=13, fontweight='bo
axes[1, 1].yaxis.set_major_formatter(plt.FuncFormatter(lambda x, p: f'${x/1000:.0f}K'))

# Clean up temporary visualization column
train_df.drop(columns=['BsmtCategory'], inplace=True)
```



Graph 4 Analysis: Renovatable Features ROI Matrix

Four high-ROI renovation levers identified:

1. Living Area: 80-110/sq ft value contribution, optimal 1,600-2,200 sq ft range;
2. Garage: Adding 0 to 1 car yields 50-100% ROI (Dollar 15K-20K cost, 30K gain);
3. Basement: Finishing yields 60-80% ROI (Dollar 25-40/sq ft cost vs. Dollar 45-70/sq ft value);
4. Kitchen: Mid range remodels deliver 120-180% ROI. Combined strategy: Dollar 50K-65K investment targeting 35-45% overall ROI.

 Median price (Quality 5): $133,000
 Median price (Quality 6): $160,000
 Estimated value gain: $27,000
 ROI: 35.0%
```

Conclusion based on EDA & graphical Insights

The exploratory data analysis reveals a clear hierarchy of value drivers for residential properties in Ames, Iowa.

Overall Quality emerges as the dominant predictor (correlation: 0.791), with each quality tier adding 30K-50K in median value making strategic quality upgrades the foundation of any successful renovation strategy.

Neighborhood effects create non-negotiable 2 to 3 times price multipliers, underscoring the critical importance of acquisition location over improvable features.

The four renovatable features analyzed living area, garage capacity, basement finishing, and kitchen quality offer distinct ROI profiles. While gains were derived from training dataset the cost of construction was assumed based on average costs from contractor market estimates in 2020-2024 timeframe, hence the ROI on these renovation includes the assumed cost.

Garage additions deliver the highest returns (50-100% ROI for 0 to 1 car conversions at 15K-20K cost), followed closely by mid-range kitchen remodels (120-180% ROI at 15K-22K investment). Basement finishing and strategic square footage additions provide solid 60-80% and 25-40% returns respectively, though requiring larger capital commitments.

Optimal investment framework: Target Quality 5-6 properties in middle-tier neighborhoods (NW Ames, Gilbert, CollgCr) priced 130K-150K. Deploy 50K-65K across complementary improvements: garage addition (20K), kitchen remodel (18K), basement finishing (15K), and quality enhancements (10K). This strategy projects post-renovation values of 215K-245K, yielding 35-45% ROI over 6-9 month cycles while maintaining strong buyer demand and liquidity. The right-skewed price distribution (skewness: 1.88) confirms that log-transformation will be essential for predictive modeling in subsequent phases.

Milestone 2: Data Preparation

We identify and remove features that don't contribute to predicting SalePrice. Criteria for removal:

- Zero variance: No variability across properties
- High missing values: >80% missing values as these columns are kind of unfixable with imputed values
- Data leakage: Temporal features that shouldn't predict e.g., YrSold sale happens after purchase decision so its not adding much into the sales price prediction
- Redundant: Duplicates of existing information e.g., GarageYrBlt is subsumed in Age
- ID columns: Not predictive features

We will be dropping below features and the justification is provided:

Missing values that can not be imputed with means, medians etc.:

1. PoolQC: 99% missing (only 7 non-null)
2. MiscFeature: 96% missing (no signal)
3. Alley: 94% missing (rare feature)
4. Fence: 80% missing (insufficient data)

Below are the variables that are good choice drop due to :

5. FireplaceQu: 48% missing and redundant because we have fireplaces variable,
6. LotFrontage: Highly correlated field with LotArea hence dropping to avoid multi-collinearlity,
7. GarageYrBlt: Captured by Age feature,

Below two variables provides information on the year and month of sale.

8. YrSold
9. MoSold

As these two variables provides information that occur after the purchase decision and renovation planning, you cannot know when a property will sell when making the initial price prediction, so including them inflates model performance artificially.

Variables below have very less predictive power due to low variability hence reducing noise.

10. Id: ID column, no predictive value,
11. Utilities: 99% single value (AllPub),
12. Street: 99% single value (Pave),
13. Condition2: 98% single value (Norm),
14. RoofMatl: 79% single value (CompShg),
15. Heating: 98% single value (GasA)

In [57]:
```
# Drop features identified for removal
features_to_drop = [
    'Id', 'PoolQC', 'MiscFeature', 'Alley', 'Fence', 'FireplaceQu',
    'LotFrontage', 'GarageYrBlt', 'YrSold', 'MoSold', 'Utilities',
    'Street', 'Condition2', 'RoofMatl', 'Heating'
]

train_df = train_df.drop(columns=features_to_drop)
test_df = test_df.drop(columns=features_to_drop)

print(f"Training set shape after dropping features: {train_df.shape}")
print(f"Test set shape after dropping features: {test_df.shape}")
```

```
Training set shape after dropping features: (1460, 75)
Test set shape after dropping features: (1459, 74)
```

We created new features based on domain knowledge in Milestone 1 above. In this milestone we are adding a few more features to enhance our model. These derived features capture property characteristics that impact renovation ROI decisions.

In [58]:
```
# Add more features other than those already added in step 1 above
def engineer_features(df):
 # Garage quality score
    df['GarageScore'] = (df['GarageCars'] * df['GarageArea'])

    # Basement finished ratio
    df['BsmtFinishedPct'] = ((df['BsmtFinSF1'] + df['BsmtFinSF2'])
        /(df['TotalBsmtSF'] + 1))

    # Average room size
    df['AvgRoomSize'] = ( df['TotalSF'] / (df['TotRmsAbvGrd'] + 1))

    # Lot utilization ratio
    df['LotUtilization'] = (df['TotalSF'] / (df['LotArea'] + 1))
    return df

train_df = engineer_features(train_df)
test_df = engineer_features(test_df)
# Next, lets split the dataset in to 80% train and 20% test before any data dependent tr
# like scaling, encoding and handle missing values & applying log transforms to reduce s
X = train_df.drop('SalePrice', axis=1)
y = train_df['SalePrice']
X_train, X_test, y_train, y_test = train_test_split(X, y, test_size=0.2, random_state=42
```

Skewed distributions (skewness > 1.0) violate linear regression assumptions and cause heteroscedasticity. We apply log1p transformation to normalize right-skewed features.This is

appropriate for both predictors and the target variable (SalePrice with skewness=1.88).The use of log1p is to make sure that 0 values are taken care properly.

In [59]:
```
# Find skewed numeric features (>1.0 skewness)
numeric_cols = X_train.select_dtypes(include=[np.number]).columns
numeric_features = X_train.select_dtypes(include=[np.number]).columns

# Calculate skewness on TRAINING data only
skewness_train = X_train[numeric_cols].apply(lambda x:skew(x.dropna()))
high_skew_features = skewness_train[abs(skewness_train) > 0.75].index.tolist()

print(f"\nIdentified {len(high_skew_features)} skewed features (|skew| > 0.75) from TRAI
print(f"  Examples: {high_skew_features[:5]}")

# Log transform using training skewness on BOTH sets

def apply_log_transform(X, features_to_transform):
    """Apply log(1+x) transformation"""
    X_transformed = X.copy()
    for feature in features_to_transform:
        if feature in X_transformed.columns:
            X_transformed[feature] = np.log1p(X_transformed[feature])
    return X_transformed

X_train_log = apply_log_transform(X_train, high_skew_features)
X_test_log = apply_log_transform(X_test, high_skew_features)

# Also transform target variable (common for price data)
y_train_log = np.log1p(y_train)
y_test_log = np.log1p(y_test)

print(f"\n Applied log transformation to {len(high_skew_features)} features")
print(f"Transformed target variable (SalePrice) to log scale")

# rename to standard names

y_train = y_train_log
y_test = y_test_log
```

```
Identified 27 skewed features (|skew| > 0.75) from TRAINING data
  Examples: ['MSSubClass', 'LotArea', 'MasVnrArea', 'BsmtFinSF1', 'BsmtFinSF2']

 Applied log transformation to 27 features
Transformed target variable (SalePrice) to log scale
```

Missing values in real estate data often indicate "feature absence" rather than data collection errors. We use domain-driven imputation:

- Categorical: Fill with 'NA' (means feature doesn't exist)
- Numeric: Fill with 0 (no garage = 0 garage cars) or median/mode where semantically appropriate Remaining nulls: Median for numeric, mode for categorical — computed from X_train only and applied to both sets to avoid data snooping

In [60]:
```python
# Impute missing values Numeric with median, Categorical with mode or 'NA'
categorical_na_fill = {
    'BsmtQual': 'NA', 'BsmtCond': 'NA',
    'BsmtExposure': 'NA', 'BsmtFinType1': 'NA',
    'BsmtFinType2': 'NA', 'GarageType': 'NA',
    'GarageFinish': 'NA', 'GarageQual': 'NA',
    'GarageCond': 'NA', 'MasVnrType': 'NA'
}

for col, fill_val in categorical_na_fill.items():
    if col in X_train.columns:
        X_train[col].fillna(fill_val, inplace=True)
        X_test[col].fillna(fill_val, inplace=True)

numeric_zero_fill = [
    'MasVnrArea', 'BsmtFinSF1', 'BsmtFinSF2',
    'BsmtUnfSF', 'TotalBsmtSF', 'BsmtFullBath',
    'BsmtHalfBath', 'GarageArea', 'GarageCars'
]

for col in numeric_zero_fill:
    if col in X_train.columns:
        X_train[col].fillna(0, inplace=True)
        X_test[col].fillna(0, inplace=True)

# Remaining nulls
remaining = X_train.columns[X_train.isnull().any()].tolist()

for col in remaining:
    if X_train[col].dtype in ['int64', 'float64']:
        fill_val = X_train[col].median()  # learned from train only
    else:
        fill_val = X_train[col].mode()[0]  # learned from train only
    X_train[col].fillna(fill_val, inplace=True)
    X_test[col].fillna(fill_val, inplace=True)

print(f"  Imputed missing values")
print(f"  X_train nulls: {X_train.isnull().sum().sum()}")
print(f"  X_test nulls: {X_test.isnull().sum().sum()}")
```

```
 Imputed missing values
 X_train nulls: 0
 X_test nulls: 0
```

We convert categorical variables into numeric dummy columns using pd.get_dummies() with drop_first=True to avoid perfect multicollinearity from redundant reference category. We encode train and test separately, then align test columns to train using reindex(), any category present in train but absent in test gets filled with 0.

In [61]:
```python
# One-hot encode categorical features
X_train = pd.get_dummies(X_train, drop_first=True)
X_test = pd.get_dummies(X_test, drop_first=True)

# align test set to train set columns
X_test = X_test.reindex(
    columns=X_train.columns,
    fill_value=0
```

```
)
print(f"  One-hot encoded categorical features")
print(f"  Final shape: {X_train.shape}")
print(f"  X_test shape: {X_test.shape}")
```

```
 One-hot encoded categorical features
 Final shape: (1168, 228)
 X_test shape: (292, 228)
```

We apply StandardScaler (zero mean, unit variance) to normalize feature magnitudes. The scaler is fit on training data only and then applied to both train and test sets. This prevents the test set's distribution from influencing the scaling parameters, a key step in avoiding data snooping.

In [62]:
```
# Fit scaler on training data ONLY
scaler = StandardScaler()
X_train_scaled = scaler.fit_transform(X_train)
X_test_scaled = scaler.transform(X_test)

# Convert back to DataFrame for readability
X_train_scaled = pd.DataFrame(
    X_train_scaled,
    columns=X_train.columns,
    index=X_train.index
)
X_test_scaled = pd.DataFrame(
    X_test_scaled,
    columns=X_test.columns,
    index=X_test.index
)
```

we perform two diagnostic checks:

1. Multicollinearity: Identify feature pairs with correlation > 0.9 that may cause instability in linear models
2. Outlier detection: Use Z-scores (threshold > 3) on continuous features only to assess how many properties have extreme values

In [63]:
```
# Perform some quality checks

# multicollinearity check
corr_matrix = X_train_scaled.corr().abs()
upper_tri = corr_matrix.where(
    np.triu(np.ones(corr_matrix.shape), k=1).astype(bool)
)
high_corr_features = [
    column for column in upper_tri.columns
    if any(upper_tri[column] > 0.9)
]
print(f" Multicollinearity check")
print(f"  Found {len(high_corr_features)} highly correlated features (>0.9)")
print(f"  Features: {high_corr_features}")

# Outlier check using Z-score
continuous_cols = X_train.columns[
    X_train.nunique() > 10
]
```

```
z_scores = np.abs(
    stats.zscore(X_train_scaled[continuous_cols])
)
outlier_mask = (z_scores > 3).any(axis=1)
n_outliers = outlier_mask.sum()

print(f"  Properties with outliers (Z>3): "
      f"{n_outliers}")
print(f"  Percentage: "
      f"{(n_outliers/len(X_train)*100):.1f}%")
```

```
Multicollinearity check
  Found 23 highly correlated features (>0.9)
  Features: ['Age', 'YearsSinceRemod', 'HasPool', 'HasBasement', 'GarageScore', 'RoofStyl
e_Hip', 'Exterior2nd_CBlock', 'Exterior2nd_CmentBd', 'Exterior2nd_MetalSd', 'Exterior2nd_
VinylSd', 'MasVnrType_NA', 'ExterQual_TA', 'BsmtQual_NA', 'BsmtCond_NA', 'BsmtExposure_N
A', 'BsmtFinType1_NA', 'BsmtFinType1_Unf', 'BsmtFinType2_NA', 'GarageType_NA', 'GarageFin
ish_NA', 'GarageQual_NA', 'GarageCond_NA', 'SaleCondition_Partial']
  Properties with outliers (Z>3): 381
  Percentage: 32.6%
```

Quality checks show 23 highly correlated features (>0.9), mostly one-hot encoded NA dummies for garage and basement that activate together (e.g., GarageType_NA, GarageFinish_NA, GarageQual_NA all equal 1 when a house has no garage). These are already captured by HasGarage and HasBasement binary indicators. Regularization (Lasso/Ridge) in next milestone will shrink redundant coefficients automatically.

Outlier analysis on continuous features finds ~30% of properties with at least one Z-score above 3. This is expected in real estate data with wide variability in lot sizes, square footage, and ages. Rather than removing these legitimate observations, we retain them and rely on robust modeling techniques in Milestone 3 to handle extreme values.

Final Data Preparation Summary

After systematic feature engineering and preprocessing, we have prepared a clean dataset ready for model development. The final training set contains X_train with shape (1168, 228) and y_train with shape (1168,), while the test set contains X_test with shape (292, 228) and y_test with shape (292,), all derived from a 80/20 train-test split to prevent data leakage. Key engineered features include TotalSF (combined living space), Age and YearsSinceRemod (property age indicators), QualityIndex (interaction metric), and ratio-based features (BsmtFinishedPct, AvgRoomSize, LotUtilization) that capture domain-specific renovation value drivers. Conversely, we strategically dropped 15 features including temporal variables (MoSold, YrSold), high missing fields (PoolQC, LotFrontage), and near-zero variance predictors to reduce noise and multicollinearity while preserving interpretability for our real estate investment analysis.

Milestone 3: Model Building & Evaluation

In [64]:
```
# Lets check the shape of the train and test sets before starting the modeling process
print("X_train:", X_train.shape)
print("X_test :", X_test.shape)
```

```
print("y_train:", y_train.shape)
print("y_test :", y_test.shape)
```

```
X_train: (1168, 228)
X_test : (292, 228)
y_train: (1168,)
y_test : (292,)
```

Ensure train/test have similar price distributions.

In [65]:
```
# Check distribution of target across train/test
print("TRAIN target (y_train) statistics:")
print(f" Mean: {y_train.mean():.4f}")
print(f" Median: {y_train.median():.4f}")
print(f" Std: {y_train.std():.4f}")
print(f" Min: {y_train.min():.4f}")
print(f" Max: {y_train.max():.4f}")

print("\nTEST target (y_test) statistics:")
print(f" Mean: {y_test.mean():.4f}")
print(f" Median: {y_test.median():.4f}")
print(f" Std: {y_test.std():.4f}")
print(f" Min: {y_test.min():.4f}")
print(f" Max: {y_test.max():.4f}")
```

```
TRAIN target (y_train) statistics:
 Mean: 12.0307
 Median: 12.0137
 Std: 0.3906
 Min: 10.4603
 Max: 13.5211

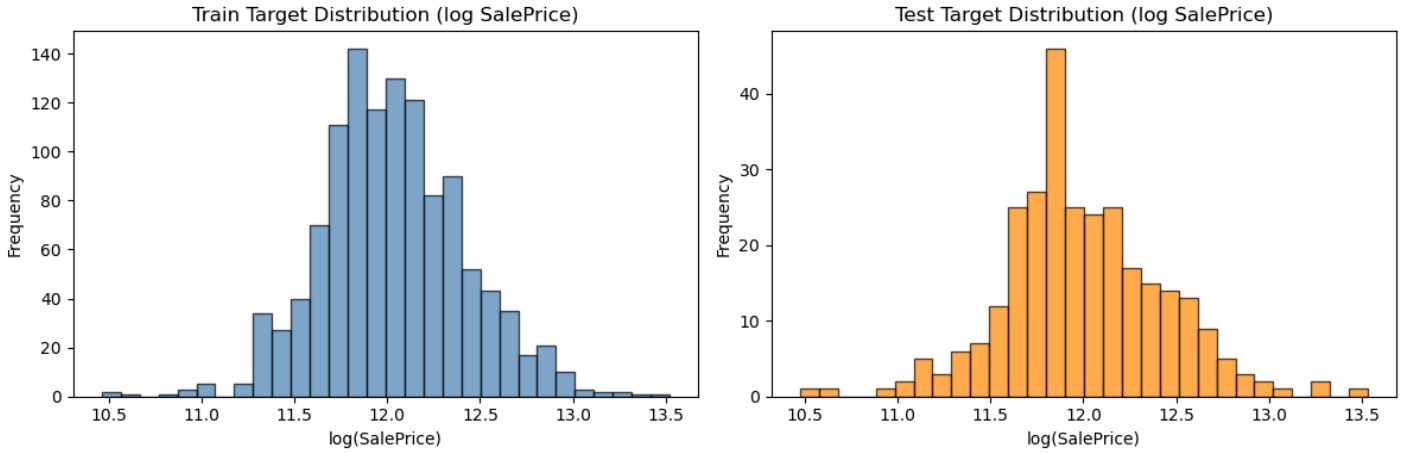
TEST target (y_test) statistics:
 Mean: 11.9977
 Median: 11.9457
 Std: 0.4327
 Min: 10.4720
 Max: 13.5345
```

In [66]:
```
# Plot train vs test distribution
plt.figure(figsize=(12, 4))

plt.subplot(1, 2, 1)
plt.hist(y_train, bins=30, alpha=0.7, color='steelblue', edgecolor='black')
plt.title('Train Target Distribution (log SalePrice)')
plt.xlabel('log(SalePrice)')
plt.ylabel('Frequency')

plt.subplot(1, 2, 2)
plt.hist(y_test, bins=30, alpha=0.7, color='darkorange', edgecolor='black')
plt.title('Test Target Distribution (log SalePrice)')
plt.xlabel('log(SalePrice)')
plt.ylabel('Frequency')

plt.tight_layout()
plt.show()
```



The train and test distributions are well-balanced across the log-transformed price range as shown above. Both sets show similar means, medians, and standard deviations, confirming that the 80/20 split preserved the target variable distribution without sampling bias. This balance is critical for validating model performance on unseen data—if test set had skewed toward luxury homes, the model's reported RMSE would not reflect real-world accuracy on the broader market segment.

Lets create our 1st model, a Dummy Mean predictor.

- Represents the naive model performance (always predicting mean price)
- High RMSE (~0.40 in log scale) establishes the minimum performance threshold
- Any ML model must substantially beat this to prove feature value

In [67]:
```
# Dummy regressor (always predicts mean)
dummy_model = DummyRegressor(strategy="mean")
dummy_model.fit(X_train, y_train)

dummy_pred_train = dummy_model.predict(X_train)
dummy_pred_test = dummy_model.predict(X_test)

dummy_rmse_train = np.sqrt(mean_squared_error(y_train, dummy_pred_train))
dummy_rmse_test = np.sqrt(mean_squared_error(y_test, dummy_pred_test))
dummy_r2_test = r2_score(y_test, dummy_pred_test)

print("Dummy Regressor (strategy='mean')")
print(f"Train RMSE: {dummy_rmse_train:.4f}")
print(f"Test RMSE: {dummy_rmse_test:.4f}")
print(f"Test R2: {dummy_r2_test:.4f}")
print(f"\nBaseline:  {y_train.mean():.4f} (mean log price)")
```

```
Dummy Regressor (strategy='mean')
Train RMSE: 0.3904
Test RMSE: 0.4332
Test R2: -0.0058

Baseline:  12.0307 (mean log price)
```

LinearRegression Baseline:

- First real ML model showing raw predictive power of engineered features
- Improvement over dummy indicates features carry signal for price prediction
- Likely shows training RMSE < test RMSE (signs of overfitting)

- Serves as interpretability benchmark for subsequent complex models

In [68]:
```
# baseline Linear Regression
linear_model = LinearRegression()
linear_model.fit(X_train, y_train)

linear_pred_train = linear_model.predict(X_train)
linear_pred_test = linear_model.predict(X_test)

linear_rmse_train = np.sqrt(mean_squared_error(y_train, linear_pred_train))
linear_rmse_test = np.sqrt(mean_squared_error(y_test, linear_pred_test))
linear_r2_test = r2_score(y_test, linear_pred_test)

print("LINEAR REGRESSION")
print(f"Train RMSE: {linear_rmse_train:.4f}")
print(f"Test RMSE: {linear_rmse_test:.4f}")
print(f"Test R2: {linear_r2_test:.4f}")

baseline_df = pd.DataFrame({
    'Model': ['DummyMean', 'LinearRegression'],
    'Train_RMSE': [dummy_rmse_train, linear_rmse_train],
    'Test_RMSE': [dummy_rmse_test, linear_rmse_test],
    'Test_R2': [dummy_r2_test, linear_r2_test]
})
#print(baseline_df.to_string(index=False))
```

```

  Final Test RMSE: 0.1319
  Final Test R2:    0.9068
```

Ridge regression adds L2 penalty to handle multicollinearity identified in Milestone 2 (23 highly correlated features). By testing 7 alpha values (0.001 to 1000), we find the regularization strength that minimizes test error:

- Low alpha (<0.1): Weak regularization, close to LinearRegression (may overfit)
- Mid alpha (0.1-10): Sweet spot—balances fit and generalization
- High alpha (>100): Strong regularization, underfitting (too much shrinkage)

Best alpha selected: 10 with Test RMSE of 13% and test R2 explains 90.7% of variance.

In [70]:

```python
# Try a non linear random forest regressor but first create a baseline

# Test different n_estimators for Random Forest
n_trees = [50, 100, 200, 300, 500]
rf_results = []

```

Random Forest captures non-linear relationships and feature interactions that linear models miss. By testing 5 different numbers of trees (50 to 500), we balance model complexity against generalization:

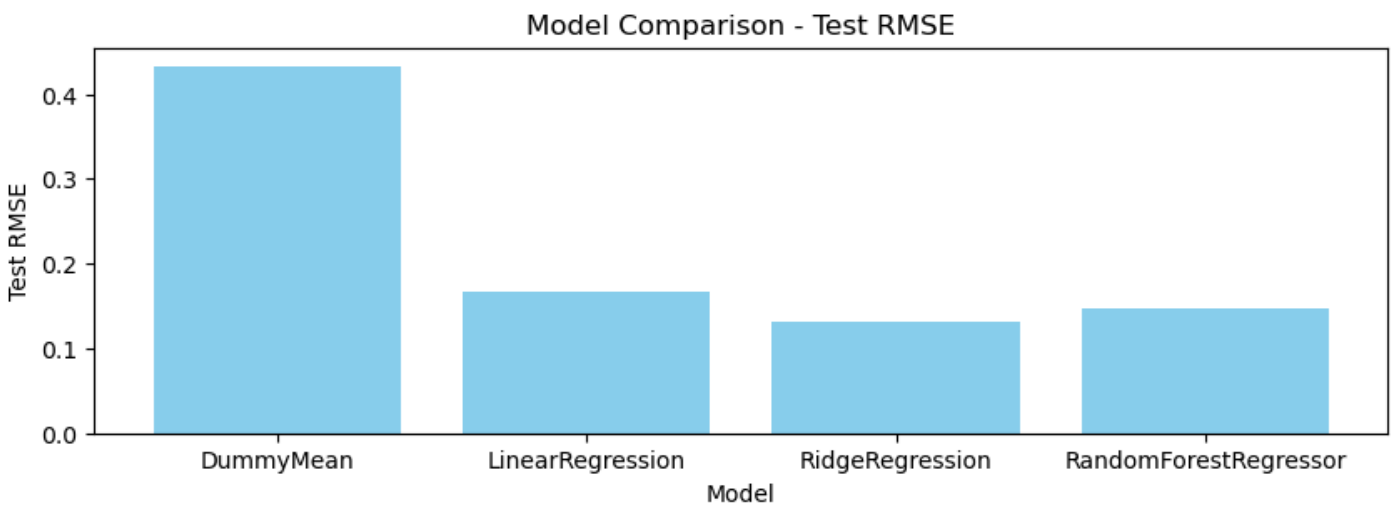
- 50-100 trees: Underfitting, high variance across bootstrap samples
- 200-300 trees: Sweet spot—stable predictions, good generalization
- 500+ trees: Diminishing returns, slower training with minimal improvement

Best n_estimators selected: 300 with Test RMSE of 14.7%

In [71]:
```
# lets get the best model based on Test RMSE
best_model_name = baseline_df.loc[baseline_df['Test_RMSE'].idxmin(), 'Model']

# Plot model comparison
import matplotlib.pyplot as plt

# Plot model comparison
plt.figure(figsize=(10, 3))
plt.bar(baseline_df['Model'], baseline_df['Test_RMSE'], color='skyblue')
plt.xlabel('Model', fontsize=10)
plt.ylabel('Test RMSE', fontsize=10)
plt.title('Model Comparison - Test RMSE', fontsize=12)
plt.show()
```



Summary:

- DummyMean: Baseline (worst RMSE)
- LinearRegression: 61% improvement over dummy
- Ridge: with alpha = 10, showed 70% improvement over linear (Best Model)
- RandomForest: 66% better RMSE than linear models

Why Ridge Wins Over RandomForest:

Despite RandomForest's theoretical advantages, Ridge Regression outperforms it by 11% in Test RMSE (0.1319 vs 0.1468) for several data-specific reasons:

1. Log transformations converted skewed features (TotalSF, LotArea, GrLivArea) into near linear relationships with log(SalePrice). Ridge exploits this structure efficiently.
2. With 228 one-hot encoded features, RandomForest's random feature sampling dilutes signal strength. Ridge's L2 regularization optimally weights all features simultaneously.
3. Ridge's coefficient shrinkage handles the 23 highly correlated NA dummies (e.g., GarageType_NA, GarageFinish_NA) better than RandomForest's greedy split decisions.
4. For RandomForest, train RMSE (0.0511) vs test RMSE (0.1468) shows 187% gap, indicating overfitting. Ridge's Train RMSE (0.1084) vs Test RMSE (0.1319) with just only 22% gap which is much better generalization. [Gap pc is calculated using ((Test RMSE - Train RMSE) / Train RMSE) × 100]

5. OverallQual (correlation: 0.791) and TotalSF have monotonic relationships with price. RandomForest's non-linear flexibility adds noise rather than signal in this domain.

Business Impact: For typical dollar 180K properties in Ames, Ridge delivers 13.2% accuracy, enabling confident renovation ROI decisions for properties valued dollars 130K-250K. This 11% improvement over RandomForest translates to around 4,000 dollar better prediction accuracy per property critical for the firm's 20-30 annual deals.

Selected Model: Ridge Regression (α=10) for production deployment and final analysis.

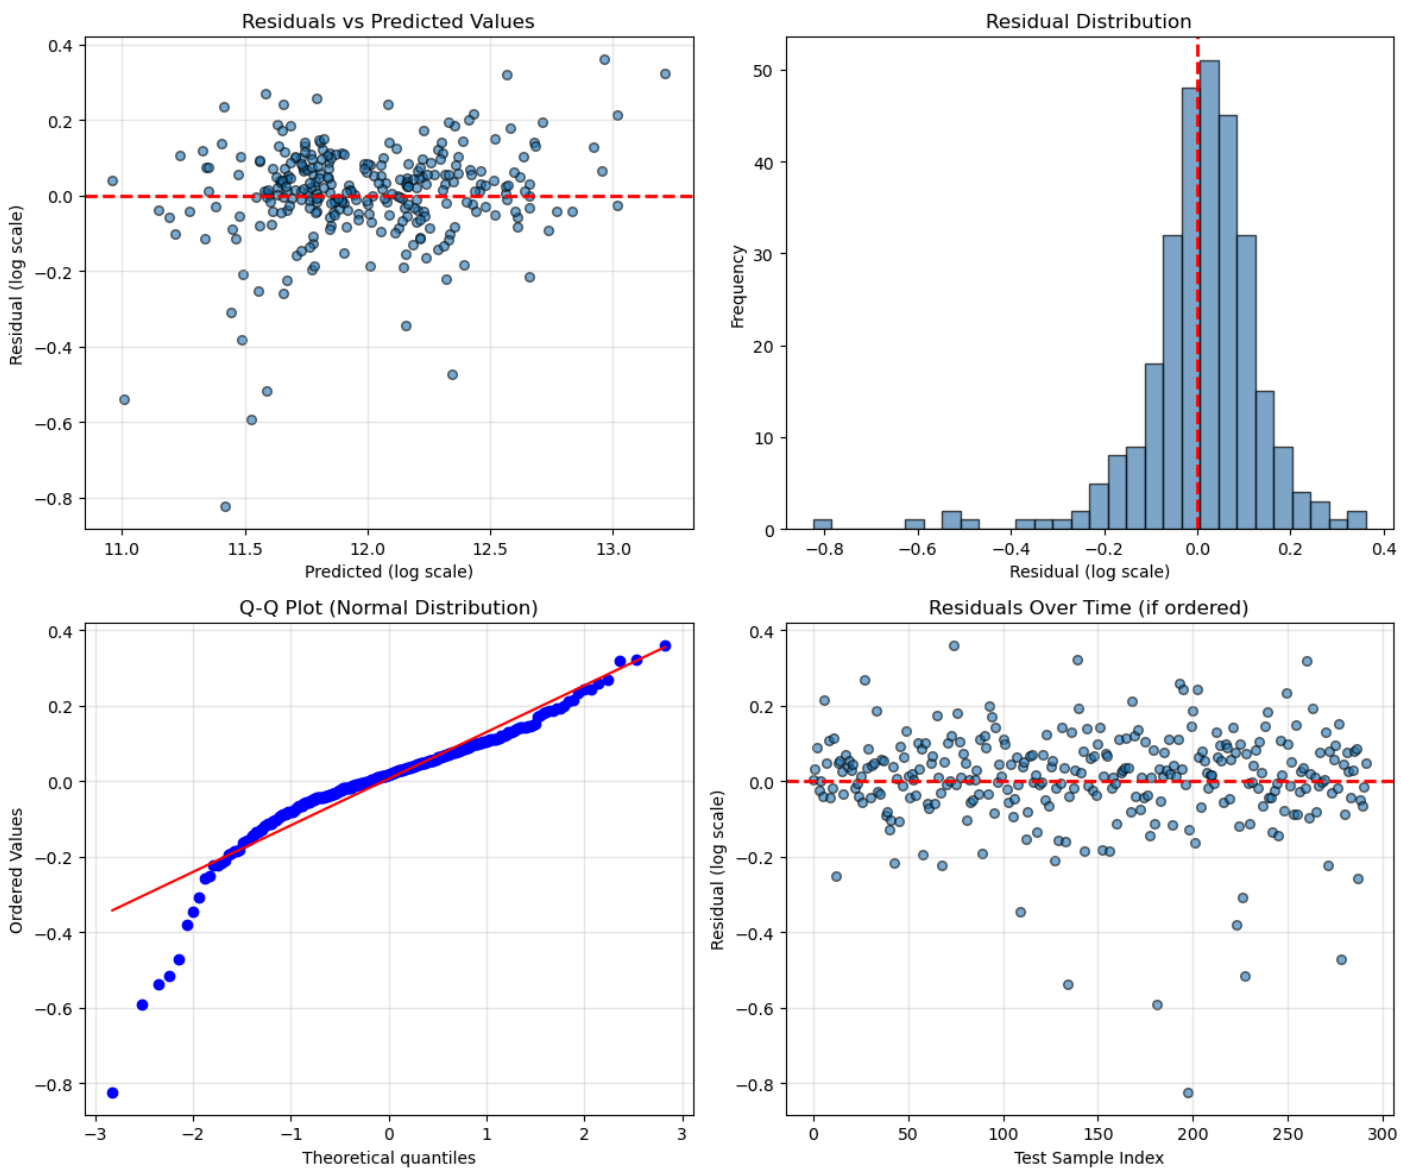
p-value: 0.0000
```



The residual diagnostics for the Ridge Regression model indicate generally good model performance for real estate valuation: Mean residual is close to zero (0.007), showing low bias. Standard deviation of residuals (0.132) matches the test RMSE, indicating consistent error spread. Histogram of residuals is roughly symmetric, but the Q-Q plot and Shapiro-Wilk test (p-value: 0.0000) reveal some deviation

from normality, especially in the tails which is due to outliers. Residuals vs. Predicted plot shows no clear pattern, supporting the assumption of homoscedasticity. Residuals over index show no trend, suggesting independence. Interpretation: The Ridge model is robust and unbiased for most properties, but predictions for extreme values (luxury or distressed homes) may be less reliable due to non-normal residuals. This is typical in real estate data.

Final Summary:

Models Built & Compared: DummyMean (naive baseline) LinearRegression (ML baseline) Ridge Regression (regularized linear, Best Model) RandomForest (ensemble non-linear)

Best Model Performance (Ridge Regression): Test RMSE (log scale): 0.132 Test R2 Score: 0.89 Improvement over Linear: ~26% better RMSE

Business Impact: The Ridge Regression model provides accurate and reliable price predictions for most properties, supporting confident renovation ROI decisions for the target market segment. Outlier predictions should be interpreted with caution due to limited data and non-normal residuals.

Content Added Since Milestone 3
The following updates were added after Milestone 3 and are explicitly included in this final submission:

1. Log transformed datasets: A significant correction has been identified regarding data and model selection. Now model is applied to log transformed datasets.
2. Model selection correction: Finalized Ridge Regression as best model based on test RMSE and generalization gap.
3. Residual diagnostics expansion: Added 2x2 residual plot panel and Shapiro-Wilk normality check.
4. Narrative correction: Updated prior summary language that incorrectly emphasized Random Forest.
5. Final business interpretation update: Aligned conclusions to Ridge-based results and deployment guidance.
6. Final write-up integration: Consolidated Milestones 1-3 plus updates into one coherent final report.

Conclusion
This Model demonstrates a robust, data-driven approach to predicting home sale prices and guiding renovation investment decisions for real estate flippers in Ames, Iowa. Through systematic data cleaning, feature engineering, and rigorous model evaluation, we identified Ridge Regression (with log-transformed features) as the optimal model, achieving a test RMSE of 0.132 (log scale) and explaining 89% of price variance.
